Thesis

Unsupervised Real-Time Time-Series Anomaly Detection

Abdul Rehman Liaquat
271336, Liaquat@uni-hildesheim.de

Abstract

Anomaly detection is a crucial task for machine learning due to wide-spread usage and type. In particular, it is worth noting that most data arising in industrial setups are of a streaming nature, thus restricting the range of standard anomaly detection tools. This thesis will identify the potential approaches to learn the identification of abnormal behavior from large-scale streaming data. An empirical comparison of state-of-the-art methods will to be extended by a novel technical contribution. In this thesis, the focus is particularly on streaming time-series Anomaly Detection which changes in nature with time and novel contribution will especially try to target this dynamic nature of time-series.

1 Introduction

1.1 Usage of streaming data

With the increase in networking of objects, amount of data being generated is increasing. A big chunk of this data involves streaming data. Streaming data can be defined as data being generated continuously or with a continuous time interval. Since streaming data is generated continuously it is highly likely that it will keep on being generated forever. Best example of such streaming data is internet of things (IoT) sensors which almost all the time generate streaming data. Statistically, IoT data has grow from 4.4ZB (Zeta Bytes) to 44.4ZB with 50 billions devices. Also it is very likely that the data will change it's shape based upon external variables which are effecting the sensor or the data generating system itself. These devices include a small temperature sensor installed in a room to ECG data to satellite communication data. Even videos are kind of streaming data since they include data points (frames) separated by a constant interval. Data generated from human mounted sensors is also streaming data. Since the data being generated is continuous and infinite in nature, it is necessary to have techniques which are using data the same way. In other words, to make use of this data it is necessary to build system which are also running live and changing themselves online. Similarly, it is important to keep the system running as often times the components which are generating streaming data are at the core of the system and in case of failure of these components, there is a danger of whole system out of service. That is why it is necessary to find out any unusual behavior of the data generated by the component. Early detection of such unusual behavior can help avoid any catastrophic impact on the system. It can also alarm the system before the break down of any thing hence acting as predictive prevention. This kind of unusal behavior is called anomaly and such detection of such unusual behavior is called anomaly detection.

An anomaly is defined as significantly different data point from other data points. The difference is dependent upon the at least two things. One is the data point being an outlier in general among all data points available. Second is that the data point value doesn't make sense in the sequence data is being generated hence it is possible for new data point to be extremely different from all previous ones but still make sense to have in the sequence and vice versa. Detecting an anomaly helps in identifying abnormal behavior of a process with potentially useful information. In normal machine learning and data science projects, anomaly and outlier detection is an important step which will help clean the data and provide useful insights. Also as described in (reference name Software2), going forward software development especially machine learning based software development will be divided into two parts. One part is the preparation of the data and the second part is the design and optimization of algorithms. Both of these steps are used iteratively. Interestingly, as described in the (reference name Software2), more and more time is spent on accumulating, massaging and cleaning datasets. One major part of this process is outlier detection, anomaly detection and novelty detection. By detection of anomalies, it will become sufficiently easy for human expert to find the one data point in a heap of millions data points and then decide whether

to remove that data or get more of the same data points.

1.2 Usage of anomaly detection in streaming data

As described above, anomaly detection is an important part of normal machine learning and data science projects. It is also very useful in streaming data systems. For example figure (1) shows real-world temperature sensor data from an internal component of a large industrial machine. Anomalies are highlighted with red background. The second anomaly was a planned shutdown hence there was an exceptional decrease in temperature. Last anomaly was a catastrophic system failure. Third anomaly just before the failure was a signal predicting the failure. If the anomaly detection system correctly detected the third anomaly system level failure could have been avoided hence saving a lot of time, money and resources.

Figure 1: Machine Temperature System Failure

Real-time data comes with special challenges and problems to solve for anomaly detection in streaming data. First constraint is the continuous arrival of data. We cannot have access to any future data. More specifically we will only have access to current time data as x_t and previous data points as $x_{t-1}, x_{t-2}, x_{t-3}, \dots$ and so on. This applies a constraint of finding the important of data in the past and update the model online. Also as the data stream

is continuous it becomes evident to have the system doing online training and prediction. Thus the first constraint of an anomaly detection algorithm is that it should train and predict online. Consider for example, in figure 2 ponents of x_t might include CPU usage for various servers, band- width measurements, latency of servicing requests, etc. At each point in time t we would like to determine whether the behavior of the system is unusual. The determination must be made in real- time, before time $t + 1$. That is, before seeing the next input (x_{t+1}), the algorithm must consider the current and previous states to de- cide whether the system behavior is anomalous, as well as perform any model updates and retraining. Unlike batch processing, data is not split into train/test sets, and algorithms cannot look ahead. Practical applications impose additional constraints on the problem. Typically, the sensor streams are large in number and at high velocity, leaving little opportunity for human, let alone expert, intervention; manual parameter tweaking and data labeling are not viable. Thus, operating in an unsupervised, automated fashion is often a necessity. In many scenarios the statistics of the system can change over time, a problem known as concept drift. Consider again the example of a production datacenter. Software upgrades and config- uration changes can occur at any time and may alter the behavior of the system figure ??

Figure 2: AWS CPU Utilization Concept Drift

In such cases models must adapt to a new definition of “normal” in an unsupervised, automated fashion. In streaming applications early detection of anomalies is valu- able in

almost any use case. Consider a system that continuously monitors the health of a cardiac patient's heart. An anomaly in the data stream could be a precursor to a heart attack. Detecting such an anomaly minutes in advance is far better than detecting it a few seconds ahead, or detecting it after the fact. Detection of anomalies often gives critical information, and we want this information early enough that it's actionable, possibly preventing system failure. There is a tradeoff between early detections and false positives, as an algorithm that makes frequent inaccurate detections is likely to be ignored. Given the above requirements, we define the ideal characteristics of a real-world anomaly detection algorithm as follows:

1. Predictions must be made online which means that the algorithm must identify state x_t as normal or anomalous before receiving the next data point x_{t+1}
2. The algorithm must learn continuously without a requirement to store the entire stream.
3. The algorithm must run in an unsupervised, automated fashion. In other words the algorithm should not be fed any labeled data or shouldn't have any manual parameter changing.
4. Algorithms must adapt to dynamic environments and concept drift, as the underlying probability distributions often change.
5. Algorithms should make anomaly detections as early as possible.
6. Algorithms should minimize false positives and false negatives.

Taken together, the above requirements suggest that anomaly detection for streaming applications is a fundamentally different problem than static batch anomaly detection. As discussed further below, the majority of existing anomaly detection algorithms (even those designed for time-series data) are not applicable to streaming applications.

1.3 Challenges to resolve

Now to define the problem officially, time series can be defined as an ordered sequence of values of a variable at equally spaced time intervals. It can be a variable or group of variables. For example a heat sensor will be producing one time series which is why it is called univariate time series. If we also consider the output of humidity sensor and noise sensor then the group of these univariate time series will be called multivariate time series. Usually techniques applied on univariate time series can also be used on multivariate after some modification. That's why we will be focusing on univariate time series only in this research thesis.

A streaming data or streaming time series has some properties specialized to it. A univariate streaming time series will have following properties:

1. Every new data point x_t will be following by a new data point x_{t+1}

2. The time difference between $t - (t - 1)*$ and $(t + 1) - t$ is approximately the same
3. There is no known ending time of the stream hence making the streaming data a major source of big data. With this requirement it becomes important to identify important part or time range of the series to be used for the processing.

Moving on there are some unique concepts related to uni-variate time series which will be helpful in the understanding of the research problem. Starting with stationary and non-stationary time series. A stationary time series is the one whose statistical properties are constant over time. These statistical properties include mean, variance and auto-correlation of the time series. Similarly with the change in one or more of these statistical properties, non-stationary time series comes into being. These non-stationary time series are also named as Concept drift. Concept drift is a terminology related to time series data specifically which is why we will be using the term Concept drift instead of non-stationary time series in future. There is also an intuitive meaning behind the name of Concept drift.

Considering that there is an underlying probability distribution in every time series and this underlying distribution is named Concept of time series such as

$$Concept = P_t(X) \quad (1)$$

The the concept drift occurs between two times t and u when the distribution or concept changes as

$$P_t(X) \neq P_u(X) \quad (2)$$

And the new data points are generated from the second distribution $p_u(X)$ onward rather than the original $P_t(X)$ for a length of time T . This time T is decided by the domain knowledge and frequency of data points. As in real life systems it is highly likely that there will be a change in the concept of the time-series hence happening of concept drift is very likely and possible. For example, there will be a concept drift in the time-series output of a heat sensor measuring the temperature of a motor of exhaust fan and the motor of the fan is changed. Thus it is necessary for our system to first recognize the concept drift. If there exists a concept drift then the model should adapt itself swiftly to avoid false positives. Similarly if there is not a concept drift then the model should not give much learning weight to these readings. Thus the model adaption according to presence of concept drift is necessary.

Time series data is the output of a streaming data from multiple devices which makes it close to impossible to label it specially for anomalies. Also due to concept drift a regular labeling needed. Since it is very difficult to label streaming time series data to detect anomalies it makes sense to do it in an unsupervised fashion. With unsupervised anomaly detection we don't need any previous labeled data and the system developed will be very generic. An anomaly is defined as a data point X_t or set of data points $X_{t-l:t}$ for which either of following is true $\gg \ll$ Example of each anomaly

1. Probability of point X_t belonging to a probability distribution ϕ is very less then the probability of previous data points X_n where $n \leq t - 1$. In other words:

$$P(X_t) \in \phi \ll P(X_n) \in \phi \quad (3)$$

This type of anomaly is called point anomaly. Here ϕ is the probability distribution generating all the data points.

2. Probability of points $X_{t-l:t}$ belonging to a probability distribution ϕ is very less then the probability of $X_{n-l:n}$ where $n \leq t - 1$. In other words:

$$P(X_{t-l:t}) \in \phi \ll P(X_{n-l:n}) \in \phi \quad (4)$$

This type of anomaly is called collective anomaly.

3. Probability of point X_t belonging to a probability distribution ϕ is almost same as the probability of previous data points X_n where $n \leq t - 1$ but the probability of point X_t belonging to a probability distribution θ is very less than the probability of point X_p belonging to θ . Here In other words:

$$P(X_t) \in \phi \approx P(X_n) \in \phi \quad (5)$$

$$P(X_t) \in \theta \ll P(X_p) \in \theta \quad (6)$$

Here θ and X_p are probability distribution and data points. θ is a distribution defined to a set of local points X_p where $p \leq t$ and p is a set of indices. This type of anomaly is called Contextual anomaly.

Now to detect all the type of anomalies described above it is necessary to estimate the underlying probability distributions responsible for generating the stream. In general there are following few steps in an Anomaly detection framework as described in figure 8.

First step is to pre-process the input data. We use min-max normalization to make sure that all input values are limited between 0 and 1. Min-max normalization can be defined as

$$z = \frac{x - \min(x)}{\max(x) - \min(x)} \quad (7)$$

Second step is to estimate the underlying probability distribution by building a model. This model can be used to model the streaming time series.

Next step would be to score the incoming data point. At this moment we will use the previously estimated probability distribution and types of anomalies defined above to score the incoming data point.

Afterwards the score is passed through a post-processing step. In this step possibly normalization and probabilistic likelihood estimation is applied on top of the previously calculated

anomaly score. In other words previously calculated anomaly score is transformed between the range of 0 and 1.

After post-processing, we can use this score to actually rank each incoming data point among previously existing data points. To label each data point as anomaly or not anomaly a thresholding procedure is necessary. Depending upon the type of post-processing extreme cases are considered as anomalies.

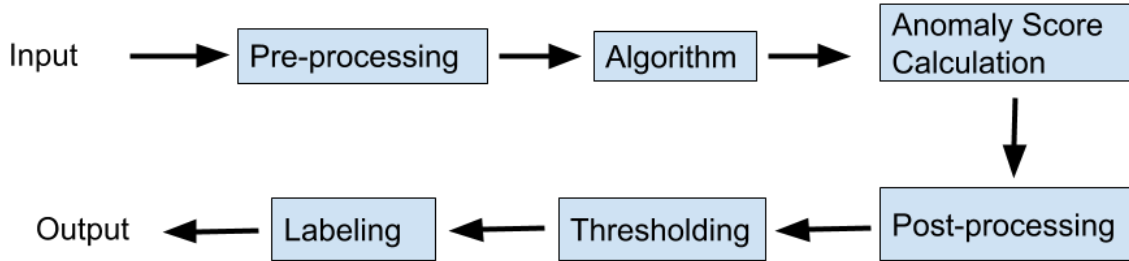

Figure 3: General Anomaly Detection Framework

Thus there are many possible points of innovation in the anomaly detection framework based upon the type of problem we are facing. A quick brief of these likely innovations are following:

1. First possible innovation is done at the pre-processing step. Here it is very helpful to normalize the input data and constrain it between 0 and 1. The benefits of normalization show up while calculating anomaly score as anomaly score will be then close to the range of 0 and 1. Another very important point is

2. Second and a major problem to solve is the algorithm that will estimate the probability distribution of streaming data. This algorithm should have at least following properties:
 - The algorithm should have the capability to differentiate the concept drift with actual anomalies and adapt itself accordingly.
 - The algorithm cannot look ahead in the future values. In other words the algorithm will work on real-time streaming data and will only be dependent upon current and past values.
 - It should be able to train itself ideally, before the arrival of next data point. This condition will make the algorithm fast and online.
3. Another possible innovation area is the values the algorithm is trained for. The algorithm can be an autoencoder based and be used to reconstruct a window of current and past values hence predicting a sequence which will then be compared with original values. The distance between the predicted sequence of reconstruction and actual values will be used as anomaly score then. Otherwise using a sub-sequence, one can predict another sub-sequence which is few time step ahead of the input sequence. The autoencoder learns how to reconstruct the current sequence and predictive learns how to predict the future values.
4. Now that we have an anomaly score, next step is to apply some post-processing on top of this score. There are two possible variations used. First variation is moving min-max normalization. With this kind of normalization current point is normalized by using the minimum and maximum values of the data obtained so far. Second type of post-processing is probability of values of a current small window from the previous values.

2 Related Work and State of the art

Here we will slowly build up to the techniques which are used in state-of-the-art anomaly detection methods. Anomaly detection in time-series has been heavily studied since a long time. Many anomaly detection approaches exist as supervised, semi-supervised and unsupervised approach. Although most of them rarely process data online. For example the robust principle component analysis (RPCA) developed by Netflix requires complete dataset to find out anomaly. Similarly EGADS developed by yahoo need access to whole data. A simpler techniques used is symbolic aggregate approximation or SAX which requires the decomposition of time series into symbols before treating them.

Anomaly detection in time-series is a heavily studied area of data science and machine learning, dating back to [5]. Many anomaly detection approaches exist, both supervised (e.g. support vector machines and decision trees [6]) and unsupervised (e.g. clustering), yet the vast majority of anomaly detection methods are for processing data in batches, and unsuitable for real-time streaming applications. Examples from industry include Netflix’s robust principle component analysis (RPCA) method [7] and Yahoo’s EGADS [8] both of which require analyzing the full dataset. Likewise, Symbolic Aggregate Approximation (SAX) [9] involves decomposing the full time series to generate symbols prior to anomaly detection. Other recent techniques include [10,11]. Although these techniques may work well in certain situations, they are traditional batch methods, and the focus of this paper is on methods for online anomaly detection. For reviews of anomaly detection in general we recommend [1,6,12,13]. For prior work on data stream mining and concept drift in general see [3,14–17]. Some anomaly detection algorithms are partially online. They either have an initial phase of offline learning, or rely on look-ahead to flag previously-seen anomalous data. Most clustering-based approaches fall under the umbrella of such algorithms. Some examples include Distributed Matching-based Grouping Algorithm (DMGA) [18], Online Novelty and Drift Detection Algorithm (OLINDDA) [19], and Multi-class learning Algorithm for data Streams (MINAS) [20]. Another example is self-adaptive and dynamic k-means [21] that uses training data to learn weights prior to anomaly detection. Kernel-based recursive least squares (KRLS) proposed in [22] also violates the principle of no look-ahead as it. Some anomaly detection algorithms are partially online. They either have an initial phase of offline learning, or rely on look-ahead to flag previously-seen anomalous data. Most clustering-based approaches fall under the umbrella of such algorithms. Some examples include Distributed Matching-based Grouping Algorithm (DMGA) [18], Online Novelty and Drift Detection Algorithm (OLINDDA) [19], and Multi-class learning Algorithm for data Streams (MINAS) [20]. Another example is self-adaptive and dynamic k-means [21] that uses training data to learn weights prior to anomaly detection. Kernel-based recursive least squares (KRLS) proposed in [22] also violates the principle of no look-ahead as it resolves temporarily flagged data instances a few time steps later to decide if they were anomalous. However, some kernel methods, such as EXPoSE [23], adhere to our criteria of real-time anomaly detection (see evaluation section below). For stream-

ing anomaly detection, the majority of methods used in practice are statistical techniques that are computation- ally lightweight. These techniques include sliding thresholds, outlier tests such as extreme studentized deviate (ESD, also known as Grubbs') and k-sigma (e.g., [24,25]), changepoint detection [26] , statistical hypotheses testing, and exponential smoothing such as Holt–Winters [27] . Typicality and eccentricity analysis [28,29] is an efficient technique that requires no user-defined parameters. Most of these techniques focus on spatial anomalies, limiting their use- fulness in applications with temporal dependencies. More advanced time-series modeling and forecasting models are capable of detecting temporal anomalies in complex scenar- ios. ARIMA is a general purpose technique for modeling temporal data with seasonality [30] . It is effective at detecting anomalies in data with regular daily or weekly patterns. Extensions of ARIMA enable the automatic determination of seasonality [31] for certain applications. A more recent example capable of handling temporal anomalies is the technique in [32] based on relative entropy. Model-based approaches have been developed for specific use cases, but require explicit domain knowledge and are not gener- alizable. Domain-specific examples include anomaly detection in aircraft engine measurements [33] , cloud datacenter temperatures [34] , and ATM fraud detection [35] . Kalman filtering is a com- mon technique, but the parameter tuning often requires domain knowledge and choosing specific residual error models [12,36–38] . Model-based approaches are often computationally efficient but their lack of generalizability limits their applicability to general streaming applications. There are a number of other restrictions that can make meth- ods unsuitable for real-time streaming anomaly detection, such as computational constraints that impede scalability. An example is Lytics Anomalyzer [39] , which runs in $O(n^2)$, limiting its useful- ness in practice where streams are arbitrarily long. Dimensionality is another factor that can make some methods restrictive. For in- stance online variants of principle component analysis (PCA) such as osPCA [40] or window-based PCA [41] can only work with high- dimensional, multivariate data streams that can be projected onto a low dimensional space. Techniques that require data labels, such as supervised classification-based methods [42] , are typically un- suitable for real-time anomaly detection and continuous learning. Additional techniques for general purpose anomaly detection on streaming data include [9,43,44] . Twitter has an open-source method based on Seasonal Hybrid ESD [45] . Skyline is another popular open-source project, which uses an ensemble of statisti- cal techniques for detecting anomalies in streaming data [24] . We include comparisons to both of these methods in our Results sec- tion.

2.1 Unsupervised Anomaly Detection

In unsupervised anomaly detection, there are five differet type of algorithms used. First type is nearest-neighbor based. These methods

1. Time series intro. Prediction and classification.
2. Unsupervised methods on time series
3. Anomaly detection

4. Time series Anomaly detection
5. Unsupervised Time series Anomaly detection
6. General components latest anomaly detection methods and explanation of each
7. HTM based anomaly detection paper review. Problems or way it does it

9. paper 3
10. general review, problems, bottlenecks and trend

3 Proposed method

3.1 General anomaly score based architecture and detailed explanation

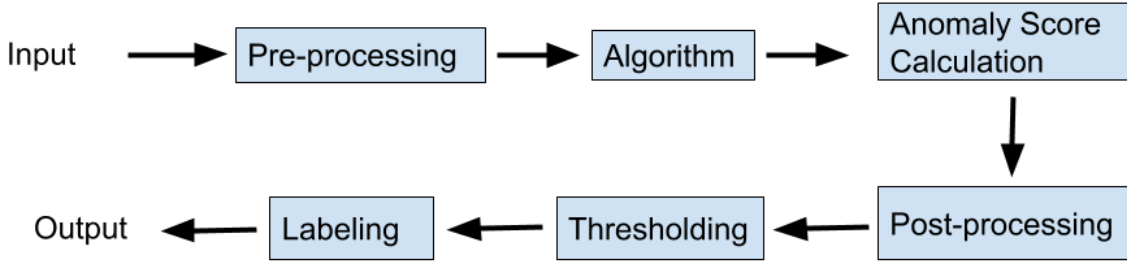

Figure 4: General Anomaly Detection Framework

Considering figure 8, each algorithm will be using all parts with few variations and a customized algorithm part.

Pre-processing is playing crucial role in the generalization of the algorithms. There are two different kind of normalization techniques tested. First kind is global normalization Proposed method can be divided in multiple parts. First part would be the implementation of baselines using latest deep learning architectural components. The main components of our anomaly detection framework are as following:

- In the pre-processing part, each time-series is normalized using equation 7. Here we assume that we already know the possible minimum and maximum values of the data

which is generally true in most cases. All the datasets are normalized before feeding into the algorithm.

- In the algorithm part, we use different kind of algorithms with few things in common. For all kind of algorithms the input values are sequence of length W and output values are also a sequence whose size is tested from 1 to 5. Another important thing to remember is that the output is different for autoencoder based architectures and multistep prediction architectures. More details are given below.
- We take the simple mean squared distance as anomaly score. So at each time step, we take the difference between the output sequence and the actual real sequence using mean squared distance. The same is also used for training of each algorithm. After doing a forward pass prediction and calculating the anomaly score using mean squared distance, we use the anomaly score to back-propagate the error using one iteration.
- Next post-processing step is important as literature shows that this step makes a significant difference in the improving the score of an anomaly detector. There are two different kind of post-processing techniques used. First technique is the usage of anomaly likelihood as described equation. The anomaly likelihood is a probabilistic metric defining how anomalous the current state is based on the prediction history. To compute the anomaly likelihood we maintain a window of the last W error values. We model the distribution as a rolling normal distribution where the sample mean μ_t and variance σ_t^2 , are continuously updated from previous error values as follows:

$$\mu_t = \frac{\sum_{i=0}^{W-1} S_{t-i}}{W} \quad (8)$$

$$\sigma_t^2 = \frac{\sum_{i=0}^{W-1} (S_{t-i} - \mu_t)^2}{W - 1} \quad (9)$$

We then compute a recent short term average of prediction errors, and apply a threshold to the Gaussian tail probability to decide whether or not to declare an anomaly. 3 We define the anomaly likelihood as the complement of the tail probability:

$$L_t = 1 - Q\left(\frac{\tilde{\mu}_t - \mu_t}{\sigma_t}\right) \quad (10)$$

and here $\tilde{\mu}_t$ is defined as:

$$\tilde{\mu}_t = \frac{\sum_{i=0}^{w-1} S_{t-i}}{w} \quad (11)$$

Here $w \ll W$. We use w for short term moving average and W for long term moving average. This will give us a probability likelihood of a data point being an anomaly. Next step is to threshold the anomaly by setting up a threshold which is defined by user and is a hyperparameter. The threshold is set to $1 - \epsilon^{-5}$

- Second method is moving mix-max normalization, which is rather simple but quite effective. We take the maximum and minimum value of the past and current data at a given point in time T and use it to normalize the incoming anomaly score value. If the new anomaly score value is greater than the past maximum value then the maximum value is updated. Similarly if the new anomaly score value is less than the past minimum value then the minimum value is updated. In the beginning of training, ususally convergence loss is higher and it does not make sense to compare it with the values calculated later on that is why first N value of the anomaly score are skipped before we start considering the maximum and minimum value. The value N is usually set around 100.

We use these components to develop two different kind of detectors.

One detector is based upon prediction of a next data point. Let $T_{(t-L-1):(t-1)}$ is the small window taken from time series. The starting point is $t - L - 1$ where L is the window size and last data point is taken from $t - 1$ which is the data point at previous time step. This data window is used to predict the time series value at time t . To predict at time t various different kind of functions as baselines using latest architectural components are designed. Generally the output of such a function would be

$$f(T_{(t-L-1):(t-1)}) = \hat{f}(t) \quad (12)$$

Thus the function f in prediction based models map data points as: $f : L \mapsto 1$ where L is the window size and output is the prediction of value at current time. For optimization of function f , the difference between time series value at current time step and predicted value at current time is taken. More specifically the objective function will be

$$\min |\hat{f}(t) - f(t)| \quad (13)$$

That is to minimize the difference between time series value at time t and predicted time series value at time t using time series value from $T_{(t-L-1):(t-1)}$.

3.2 Autoencoder based architecture

An autoencoder is a network which is trained to copy its input to its output, with the typical purpose of dimension reduction - the process of reducing the number of random variables under consideration. It features an encoder function to create a hidden layer (or multiple layers) which contains a code to describe the input. There is then a decoder which creates a reconstruction of the input from the hidden layer. An autoencoder can then become useful by having a hidden layer smaller than the input layer, forcing it to create a compressed representation of the data in the hidden layer by learning correlations in the data. This compressed representation is actually summarized version of input. This way for the anomaly input values, summarized version will not output very similar output and hence ending up

creating big reconstruction loss. The backpropagation will try to $h_{W,b}(x) \approx x$, so as to minimise the mean square difference:

$$L(x, y) = \sum (x - h_{W,b}(x))^2 \quad (14)$$

Similarly for time series let X_t be the input value of the streaming data at time t then the input of autoencoder based architecture will be $X_{t-w:t}$ and output will be $Y_{t-w:t}$ as Y is the predicted reconstruction of the input.

$$Y_{t-w:t} = h(X_{t-w:t}) \quad (15)$$

The reconstruction loss is defined as:

$$L(x, y) = \frac{1}{w} \sum (Y_{t-w:t} - X_{t-w:t})^2 \quad (16)$$

»» picture of an autoencoder

3.3 Multistep-Ahead based architecture

»» picture of an multi-step based architecture Second type of architecture used is multi-step prediction architecture. In this type of architecture For time series let X_t be the input value of the streaming data at time t then the input of multistep prediction based architecture will be $X_{t-w-l:t-l}$ and output will be $Y_{t-l:t}$ as Y is the prediction of the input. More specifically

$$Y_{t-l:t} = h(X_{t-w-l:t-l}) \quad (17)$$

and the prediction loss will be defined as:

$$L(x, y) = \frac{1}{l} \sum (Y_{t-l:t} - h(X_{t-w-l:t-l}))^2 \quad (18)$$

Above two are the basic outputs which are repeated with following different architectures.

4 Empirical Formulation and Experiments

4.1 Dataset

To experiment with proposed method and compare them with state-of-the-art results Numenta Anomaly Benchmark (NAB) was used. Numenta is a benchmark specifically designed for online time series anomaly detection.

Using NAB provides with many benefits. First is a benchmark dataset which 58 various univariate time series, each with timestamp as index and value. Length of each time series ranges from 1000 to 22000 data points. These 58 time series are from six different categories. These categories include artificially generated time series, times series gathered from advertisement industry related data such as click through rate (CTR), AWS usage metrics, server traffic data, tweets volume time series and known cause anomaly which has the a solid reason for the labeled anomaly.

The diversity of these categories provide the second benefit. With the diversity almost all type of anomalies are covered hence each algorithm can be tested against each type. Artificial datasets further contains time series with anomalies and without anomalies. Datasets without anomalies contain only normal patterns and no anomaly thus any predicted anomaly will be a false positive here.

(b) Artificial with sudden jumps-down

(c) Artificial with sudden jumps-up

(d) Artificial with sudden flat

Figure 9: Examples of artifical anomaly data set

Many datasets contains concept drift. These datasets are mostly real life ones. Example of these are following:

(a) Artificial with sudden flat-middle

(b) Artificial with sudden jumps-down

(c) Artificial with sudden jumps-up

(d) Artificial with sudden flat

Figure 10: Examples of Concept drift in AWS data sets

Similarly almost all kind of anomalies exist in the dataset. For example for point anomaly we can see that in following.

Figure 11: Examples of point anomalies from twitter volume dataset

Another important benefit is the availability of labeled data. Other than the seven time series for which we know the existence of anomaly, others were labeled using following process.

1. A number of human labelers have labeled the benchmark dataset. Each individual labeler read through the published labeling guidelines, and then looked through the individual data files in the benchmark dataset, using data visualization methods. They recorded the timestamps at which anomalies appeared to start. The collection of these labels for all the data files makeup the raw labels files, one for each labeler and data batch.
2. Each raw label file is a dictionary of key-value pairs, where the dataset name identifies a list of labeled anomaly timestamps. Across these files, the timestamps are compared to identify the ground truth anomalies, yielding one ground truth label file. To determine the true anomalies, a custom “bucket-merge” algorithm is used:
 - (a) For each given data file (i.e. the key), the start timestamps from all the raw labels are collected into buckets with other start timestamps within a certain range. That is, timestamps within a narrow range of one another are bucketed together

because they (very likely) identify the same anomaly. Differences in anomaly start times amongst labelers can be attributed to human error. The size of the time range is set as $1/10$ the size of an anomaly window (defined in step 3 below), both preceding and following the given timestamp. The rationale is straightforward: following the underlying assumption anomalies are rare, if multiple anomaly labels fall within the same window, they identify the same sequence of anomalous data.

- (b) If a given bucket contains more timestamps (raw labels) than the agreement threshold, it is classified as a true anomaly. The standard threshold is 0.50, so a bucket must contain timestamps from 50% or more of the labelers in order to become a true anomaly label .
 - (c) Each true anomaly bucket is then merged into a single timestamp based on frequency. That is, the timestamp which appears most often within a bucket is chosen to represent the entire bucket. Ties are determined by which timestamp occurs first. The resulting timestamps are the ground truth labels marking the start of the true anomalies.
3. The combined labels are then converted into anomaly windows, indicated by a beginning and ending timestamp. The motivation behind anomaly windows is twofold. First, anomalous data often occurs over time, rather than at a single point, and thus defining anomaly windows improves the NAB scoring efficacy. Second, anomaly windows allow the DUT to not be penalized during scoring if the DUT anomaly detections are slightly before or after the ground truth. We want these windows to be large enough to allow early detection of anomalies, but not so large as to artificially boost the score of inaccurate detectors. That is, the windows give the benefit of the doubt to the detector, but not so much that false positives would count as true positives. The anomaly windows are calculated using the following algorithm:
- (a) The total amount of window length in a single data file was chosen to be 10% of the data file length. For instance, if a data file contains 4000 data points, then the total amount of relaxation shared by all anomaly windows in the data file is 0.1×4000 , or 400 data points. The 10% parameter was validated by qualitatively inspecting the dataset, and experimenting with a range of values showed no significant affect on the resulting scores, likely due to the scaled sigmoid scoring function (described later).
 - (b) The total window length for a data file is then divided by the total number of ground truth anomalies in the data file, and the resulting number of data points makeup each anomaly window, $1/2$ before the start of the window, and $1/2$ at the end of the window. For instance, if the data file above has four ground truth anomalies, then each anomaly window is $400/4$, or 100 data points – i.e. 50 data points both before and after the truth anomaly data point.
 - (c) If two ground truth anomalies are in close proximity such that they overlap, the anomalies are combined into one large window. The rationale being if multiple

anomalies fall within the same window length, we assume they identify the same anomalous data.

Thus ground labels of anomalies are obtained.

5 Results

5.1 Scoring

Another benefit of using NAB is that it comes with a customized scoring and evaluation mechanism which is quite suitable for the online anomaly detection algorithms. Each algorithm is tested against three different profiles. Each profile provides a specific weight to true positive (TP), false positive (FP) and false negative (FN). This way an algorithm can be tested according to the requirement of the system.

The value of the TP weight in the default application profile is 1.0. If a user wants to emphasize the importance of correct anomaly detection during the benchmark run, then the TP weight metric can be increased. This will increase the amount that the score is incremented every time an anomaly is detected correctly. Accordingly, if the user wants to deemphasize the importance of correct anomaly detection during the benchmark run, then lowering the value of the TP weight will decrease the amount added to the score every time an anomaly is detected correctly.

The value of the FP weight in the default application profile is 1.0. If a user doesn't care as much about false positives being detected, then decreasing this value will decrement the score by a lesser amount every time an anomaly is incorrectly identified. Accordingly, if the user wants to emphasize a low FP rate, then increasing the value of FP will decrement the score by a greater amount every time an anomaly is incorrectly identified.

In case of FN weight, the score is reduced by this amount once for each anomaly which is not detected at all. The value of the FN weight in the default application profile is 1.0. If a user wants to make it more important that the detector never miss a real anomaly, then increasing the FN weight will decrement the score by a greater amount when an anomaly is missed. If the user cares less about true anomalies being missed, then decreasing the value of the FN weight will decrement the score by a lesser amount when an anomaly is missed.

With the anomaly windows defined to be 10% of a given data file, true positives are limited to 10% of the data. Yet false positives can occur in 90% of the data. That is, of all the timesteps in each data file, only 10% are eligible to be true positives (within a window), while 90% can be false positives (outside a window). Thus we scale the score contribution of false positives such that they have the same cumulative weight as true positives – i.e. the score contributions from false positives are divided by 9. This is reflected in the application profiles below.

As described above, with the combination of true positive (TP) weight, false positive (FP) weight and false negative (FN) weight, NAB creates three application profiles. The main one is **standard profile** which attributes equal weight across the scoring metrics. To be specific TP weight is set to 1, FP to 1 and FN to 0.11.

Second profile rewards a detector that has a very low FP rate; they would rather trade off missing a few true anomalies rather than getting multiple false positives. The scoring weights are set as following:

- true positive weight is set to 1. This will give full credit to properly detected anomalies.
- false positive weight is set to 0.22. This will decrease the score for any false positive.
- false negative weight is set to 0.5. This is bigger than FP weight. Thus the algorithm will be rewarded for low false positives.

Last application profile will reward a detector that does not miss any true anomalies; they would rather trade off a few false positives than miss any true anomalies. The scoring weights are set as true positive weight is set to 1. false positive weight is set to 0.055. False negative weight is set to 2.

NAB then uses above profiles to come with a scoring function. The given scoring function is built around the ideal real-world anomaly detector. The characteristics of an ideal real-world anomaly detector should be:

1. detects all anomalies present in the streaming data
2. detects anomalies as soon as possible, ideally before the anomaly becomes visible to a human
3. triggers no false alarms (no false positives)
4. works with real time data (no look ahead)
5. is fully automated across all datasets (any data specific parameter tuning must be done online without human intervention) To promote early detection NAB defines anomaly windows. Each window represents a range of data points that is centered around a ground truth anomaly label.

Figure 12: Scoring example for a sample anomaly window, where the values represent the scaled sigmoid function. The first point is an FP preceding the anomaly window (red dashed lines) and contributes -1.0 to the score. Within the window we see two detections, and only count the earliest TP for the score. There are two FPs after the window. The first is less detrimental because it is close to the window, and the second yields -1.0 because it's too far after the window to be associated with the true anomaly. TNs make no score contributions. The scaled sigmoid values are multiplied by the relevant application profile weight. The NAB score for this example would calculate as: $-1.0A_{FP} + 0.9999A_{TP} - 0.8093A_{FP} - 1.0A_{FP}$

To promote early detection NAB defines anomaly windows. Each window represents a range of data points that is centered around a ground truth anomaly label. Fig. 2 shows an example using the data from Fig. 1. A scoring function (described in more detail below) uses these windows to identify and weight true positives, false positives, and false negatives. If there are multiple detections within a window, the earliest detection is given credit and counted as a true positive. Additional positive detections within the window are ignored. The sigmoidal scoring function gives higher positive scores to true positive detections earlier

in a window and negative scores to detections outside the window (i.e. the false positives). These properties are illustrated in Fig. 3 with an example. How large should the windows be? The earlier a detector can reliably identify anomalies the better, implying these windows should be as large as possible. The tradeoff with extremely large windows is that random or unreliable detections would be regularly reinforced. Using the underlying assumption that true anomalies are rare, we define anomaly window length to be 10% the length of a data file, divided by the number of anomalies in the given file. This technique allows us to provide a generous window for early detections and also allow the detector to get partial credit if detections are soon after the ground truth anomaly. 10% is a convenient number but note the exact number is not critical. We tested a range of window sizes (between 5% and 20%) and found that, partly due to the scaled scoring function, the end score was not sensitive to this percentage. Different applications may place different emphases as to the relative importance of true positives vs. false negatives and false positives. For example, the graph in Fig. 2 represents an expensive industrial machine that one may find in a manufacturing plant. A false negative leading to machine failure in a factory can lead to production outages and be extremely expensive. A false positive on the other hand might require a technician to inspect the data more closely. As such the cost of a false negative is far higher than the cost of a false positive. Alternatively, an application monitoring the statuses of individual servers in a datacenter might be sensitive to the number of false positives and be fine with the occasional missed anomaly since most server clusters are relatively fault tolerant. To gauge how algorithms operate within these different application scenarios, NAB introduces the notion of application profiles. For TPs, FPs, FNs, and TNs, NAB applies different relative weights associated with each profile to obtain a separate score per profile.

NAB includes three different application profiles: standard, reward low FPs, and reward low FNs. The standard profile assigns TPs, FPs, and FNs with relative weights (tied to the window size) such that random detections made 10% of the time would get a zero final score on average. The latter two profiles accredit greater penalties for FPs and FNs, respectively. These two profiles are somewhat arbitrary but designed to be illustrative of algorithm behavior. The NAB codebase itself is designed such that the user can easily tweak the relative weights and re-score all algorithms. The application profiles thus help evaluate the sensitivity of detectors to specific applications criteria. The combination of anomaly windows, a smooth temporal scoring function (details in the next section), and the introduction of application profiles allows researchers to evaluate online anomaly detector implementations against the requirements of the ideal detector. Specifically the overall NAB scoring system evaluates real-time performance, prefers earlier detection of anomalies, penalizes “spam” (i.e. FPs), and provides realistic costs for the standard classification evaluation metrics TP, FP, TN, and FN.

Now to compute NAB score for an algorithm and a given application profile we use following procedure. Let A be the application profile under consideration, with A_{TP} , A_{FP} , A_{FN} and A_{TN} the corresponding weights for true positives, false positives, false negatives

and true negatives. These weights are bounded $A_{TP} \geq 0$, $A_{TN} \leq 1$ and $A_{FP} \leq -1$, $A_{FN} \leq 0$. Let D be the set of data files and let Y_d be the set of data instances detected as anomalies for datafile d . (As discussed earlier, we remove redundant detections: if an algorithm produces multiple detections within the anomaly window, we retain only the earliest one.) The number of windows with zero detections in this data file is the number of false negatives, represented by f_d . The following scaled sigmoidal scoring function defines the weight of individual detections given an anomaly window and the relative position of each detection:

$$\sigma^A(y) = (A_{TP} - A_{FP})\left(\frac{1}{1 + e^{5y}}\right) - 1 \quad (19)$$

In equation (19), y is the relative position of the detection within the anomaly window. The parameters of the equation are set such that the right end of the window evaluates to $\sigma(y = 0.0) = 0$ and it yields a max and min of A_{TP} and A_{FP} , respectively. Every detection outside the window is counted as a false positive and given a scaled negative score relative to the preceding window. The function is designed such that detections slightly after the window contribute less negative scores than detections well after the window. Missing a window completely is counted as a false negative and assigned a score of A_{FN} . The raw score for a data file is the sum of the scores from individual detections plus the impact of missing any windows:

$$S_d^A = \left(\sum_{y \in Y_d} \sigma^A(y)\right) + A_{FN}f_d \quad (20)$$

Equation (20), accumulates the weighted score for each true positive and false positive, and detracts the total score with a weighted count of all the false negatives. The benchmark raw score for a given algorithm is simply the sum of the raw scores over all the data files in the corpus:

$$S^A = \sum_{d \in D} S_d^A \quad (21)$$

The final reported score is a normalized NAB score computed as follows:

$$S_{NAB}^A = 100 \times \frac{S^A - S_{null}^A}{S_{perfect}^A - S_{null}^A} \quad (22)$$

Here we scale the score based on the raw scores of a “perfect” detector (one that outputs all true positives and no false positives) and a “null” detector (one that outputs no anomaly detections). It follows from equation (22) that the maximum (normalized) score a detector can achieve on NAB is 100, and an algorithm making no detections will score 0.

6 Conclusion and Discussion

7 Experiment Infrastructure

7.1 Experiment Management using MLflow

7.2 Parallel execution using Docker

8 Best practices

Following steps were taken to maximize the efficiency and speed of research:

1. Use version control to track the code and share between different devices.
2. Separate code from data. This will keep the code base small and easy to debug.
3. Separate input data, working data and output data.
 - **Input Data:** Input data-set that never change. For my case it is NAB and other external datasets.
 - **Working Data:** nothing for now.
 - **Output Data:** Results and threshold profiles in my case.
4. Separate options from parameter. This is important:
 - Options specify how your algorithm should run. For example data path, working directory and result directory path, epochs, learning rate and so on.
 - parameters are the result of training data. it includes the score and hyper-parameters.

8.1 Moving from jupyterlab to pycharm

While working with jupyterlab notebook following routine was followed: 1- Load data with sample function 2- Write an algorithm 3- Test the results 4- Write general executeable .py file. 5- Get results on server

Since we needed to track change on two different places, it was becoming harder to track the bugs and improve on efficiency. That's why pycharm was selected to create executeable files and test algorithms at the same time.
